Matrices with small Coherence using $p$-ary Block Codes

Arash Amini*, Vahid Montazerhodjat, and Farokh Marvasti, Senior Member, IEEE

Abstract—In contrast to the vast amount of literature in random matrices in the field of compressed sensing, the subject of deterministic matrix design is at its early stages. Since these deterministic matrices are usually constructed using the polynomials in finite Galois fields, the number of rows (number of samples) is restricted to some specific integers such as prime powers. In this paper, besides extending a previous matrix design based on the binary BCH codes to the $p$-ary codes, we introduce matrices with wide variety of options for the number of rows. Simulation results demonstrate that these matrices perform almost as well as random matrices.

Index Terms—Compressed Sensing, $p$-ary BCH codes, Coherence.

I. INTRODUCTION

The technique of compression while sampling, usually referred to as Compressed Sensing, has been the center of attention for at least half a decade [1]–[3]. In fact, the compressibility of the discrete data associated with an analog signal such as speech and image indicates that the sampling procedure is not as efficient as possible; i.e., instead of compressing the data after the sampling procedure, there should be a method to combine these two tasks (sampling and compression) in order to somehow decrease the rate.

In the field of discrete compressed sensing, we are interested in reconstructing a $k$-sparse $n \times 1$ source vector, namely $x_{1 \times n}$, from its linear projections onto an $m \times 1$ measurement vector ($y_{m \times 1}$). The measurement process is theoretically assumed to be linear in the form of $y_{m \times 1} = \Phi_{m \times n} x_{1 \times n}$, where $\Phi_{m \times n}$ is called the sensing matrix. Moreover, the vector $x$ is assumed to be $k$-sparse which means that $x$ has a sparse representation in a (known) unitary domain, namely, $x_{1 \times n} = \Psi_{1 \times n} s_{1 \times 1}$ where $s$ has at most $k$ nonzero elements and $\Psi$ is a unitary matrix. In this paper, we assume that $\Psi$ is the identity matrix or equivalently, we are considering $\Phi$ instead of $\Phi \Psi$.

The two main problems in the discrete compressed sensing are the sampling and reconstruction tasks. The sampling part consists of designing a proper sensing matrix $\Phi_{m \times n}$ with small enough $m$ (number of samples) that preserves the main information conveyed by the original signal. The common solution is to use a random matrix of i.i.d. elements with $m \geq O(k \log n)$ (we hereafter refer to this inequality as the bound in the random theory); the Gaussian distribution is probably the first studied case [1], however, a large class of distributions are investigated in [4]. The reconstruction challenge is to recover the original vector from an under-determined system of linear equations ($m$ equations vs. $n$ unknowns) with the additional sparsity constraint. This problem has a longer research history as it also appears in the source separation problems. Although the mentioned problem is intractable in general [5], under certain conditions, it is shown that $\ell_1$ minimization (basis pursuit) can yield the desired result [2], [5]. Also the greedy algorithms such as matching pursuit and its variants, due to their reasonable computational complexity, are among the well-known techniques in this field [6].

Although a realization of a random sensing matrix, with high probability provides the possibility of perfect recovery for all $k$-sparse vectors with small enough value of $k$, there is currently no polynomial-time algorithm to verify this property for a given matrix. The main benefit of deterministic designs is that stable recovery of sparse vectors can be guaranteed without any probabilistic arguments. Among other advantages of the deterministic designs is the storage issue; to store a realization of a random matrix, all the elements should be kept in the memory and the process should be repeated each time a new realization is generated, while in deterministic designs, because of the special structure of the matrix, only a few parameters should be stored. Furthermore, deterministic matrices are likely (eg. the matrices introduced in this paper) to provide simplicity in both sampling and reconstruction processes.

One of the main tools for investigating the suitability of a given matrix as a sensing operator is the so called Restricted Isometry Property (RIP) introduced in [2]; the matrix $\Phi_{m \times n}$ is said to satisfy the RIP of order $k$ with constant $0 \leq \delta_k < 1$ if for every $k$-sparse vector $s$, the following inequalities hold:

$$\forall s_{1 \times 1} : k \text{-sparse} \quad 1 - \delta_k \leq \frac{||\Phi s||_2^2}{||s||_2^2} \leq 1 + \delta_k. \quad (1)$$

It should be mentioned that RIP is only a necessary condition that guarantees recovery; there are examples where RIP-less guarantees support special type of sensing matrices [7]–[10].

The coherence of a matrix defined as

$$\mu_A \triangleq \max_{i \neq j} \frac{|\langle a_i, a_j \rangle|}{||a_i|| \cdot ||a_j||} \quad (2)$$

where $a_i, a_j$ are different columns of $A$, is one of the main tools for establishing the RIP in deterministic matrices. In
plain words, matrices with normalized columns are guaranteed to satisfy an RIP order when the coherence is small [11, 12]. There is a well-known lower bound on the coherence of an $m \times n$ ($m < n$) matrix $A$ known as Welch bound [13]:

$$\mu_A \geq \frac{n}{m(n - m)}.$$  \hspace{1cm} (3)

The above lower bound implies an upper bound on the provable RIP order of a matrix through coherence arguments. Unfortunately, this upper bound is proportional to $\sqrt{m}$ while for the random matrices, the upper bound scales like $m$; i.e., there is inherently a gap between the RIP orders that are guaranteed for deterministic designs and the ones predicted by the random matrices.

In [11], using the coherence arguments, DeVore has proposed $p^2 \times p^{l+1}$ binary matrices with coherence $\frac{\sqrt{p}}{p}$ that satisfy the RIP of order $k$ when $kr < p$. Exploiting the hash functions and extractor graphs, another class of binary matrices with $m = k2^{O(\log \log n)}$ ($m \times n$ matrix with RIP of order $k$) has been introduced in [14]; here $E$ is a constant larger than 1 which is involved in the construction of the extractor graphs (the best known guarantee is $E = 2$). In addition to the extractor graphs, expander graphs are also shown to be useful for sensing purposes [7], [15]. The authors in [16] have established a connection between Compressed Sensing (CS) and coding theory, specifically the second order Reed-Muller codes and have proposed a category of bipolar $2^r \times 2^{l+1}$ deterministic sensing matrices; however, no lower bound on the RIP order of these matrices is proved. Some $m \times m^2$ complex-valued matrices have been investigated in [17] by taking advantage of chirp functions; although there is no guarantee for the RIP order of these matrices, in [18], a relaxed version of the RIP known as Statistical RIP (SiRIP$^+$), is shown to hold. In fact, a more general class of SiRIP matrices are introduced in [18]: it is shown that if 1) the rows of a matrix $A_{m \times n}$ are orthogonal and all the row sums are zero, 2) the columns of the matrix form a group under point-wise multiplication, and 3) the absolute value of the column sums except the all-one column, are upper bounded by $m^{1-(0.5\eta)}$ for $\eta > 0.5$, then the inequalities in (1) hold with high probability over all $k$-sparse vectors for the matrix $\overline{\overline{A}}$ when $k < 1 + (n-1)\eta$ and $m \geq \left(\frac{\mu}{\sqrt{p}}\right)^\frac{1}{2}k\log n$ for some constant $c$.

In [12], using coherence arguments and based on the BCH codes, we have recently introduced $(2^l - 1) \times 2^{O(2^{l+1} / \sqrt{p})}$ bipolar matrices with $\mu \leq \frac{2^{l+1}}{\sqrt{p}}$. Although, the use of BCH codes in compressed sensing and dimensionality reduction has been already investigated (e.g., [18], [19]), the approach and results in [12] which are generalized in this paper, are different in that, there is no randomness involved, neither in the matrix nor in the type of recovery guarantees.

Unlike the Devore’s matrices for which the coherence is lower bounded by Johnson’s bound (see [20] or [12] for the explanation of the bound) rather than the Welch bound, the coherence of the BCH-based matrices in [12] is relatively close to the Welch bound. However, the number of rows ($m$) in these matrices are restricted to the forms $2^l - 1$ (there are more options in Devore’s design). In this paper, we generalize the utilization of the binary BCH codes to the use of $p$-ary codes (where $p$ is a prime integer) and obtain $m \times n$ complex-valued sensing matrices; the details of these matrices are shown in Table I (the matrices in [12] are special cases when $p = 2$). This generalization, not only increases the possible options for $m$, but also results in matrices with a coherence closer to the Welch bound as $p$ increases. We further broaden the achievable range of options by introducing two techniques for combining matrices with small coherence. The first is the Kronecker product which is of special interest for changing the number of rows. In the second method, we combine a binary matrix with fixed column weight and another matrix with fixed absolute value of the elements. This technique increases the number of columns in the binary matrix without increasing the number of rows or the coherence.

The rest of the paper is organized as follows: in Sec. II we explain how block codes, specially $p$-ary codes, can form sensing matrices with small coherence. Here we briefly review the concepts of the binary design in [12] and highlight the challenges for generalizing to $p$-ary codes. Section III describes a $p$-ary code design suitable for generating sensing matrices. The method is completely deterministic (no search is required) and is based on the generalized BCH codes. Due to the use of $p$-ary BCH codes, the number of rows in these matrices are restricted to the form $p^l - 1$ for some integer $l$; in Sec. IV, we show that by using the Kronecker product of these matrices, we can achieve matrices with more options on the number of rows. Other than the Kronecker product, we present a technique for combining binary and $p$-ary matrices which increases the number of columns without changing the number of rows. The simulation results in Sec. V confirm that the BCH-based matrices perform almost similar to the random matrices; here we consider different scenarios including real images. Finally, Sec. VI concludes the paper.

II. COMPLEX MATRICES VIA $p$-ARY LINEAR CODES

In this section, we explain how block codes, specially $p$-ary codes, can form sensing matrices with small coherence.

In the case of SiRIP, for a given and fixed matrix, the inequalities in (1) hold with high probability if the support of the $k$-sparse vector is drawn uniformly at random from all the $\binom{n}{k}$ possible ways and the non-zero elements follow an independent and identical Gaussian distribution.
Since the approach is based on the one used for bipolar matrices introduced in [12], we briefly discuss the binary design concepts.

Assume that we are given a \((\tilde{n}, \tilde{k})\) linear binary code\(^2\) with the minimum distance \(\tilde{d}_{\text{min}}\) such that the all-one vector \((1_{\tilde{n} \times \tilde{1}})\) is a valid codeword; due to the linearity of the code, all-zero vector \((0_{\tilde{n} \times \tilde{1}})\) is always a codeword. Now for all pairs of code vectors such as \(a_{\tilde{n} \times \tilde{1}}, b_{\tilde{n} \times \tilde{1}}\) with \(c_{\tilde{n} \times \tilde{1}} \triangleq a \oplus b\) (\(\oplus\) denotes the bitwise XOR operation), one of the following statements is true:

1. \(c_{\tilde{n} \times \tilde{1}} = 0_{\tilde{n} \times \tilde{1}}\) or \(1_{\tilde{n} \times \tilde{1}}\).
2. \(c_{\tilde{n} \times \tilde{1}} \neq 0_{\tilde{n} \times \tilde{1}}\) and \(c_{\tilde{n} \times \tilde{1}} \neq 1_{\tilde{n} \times \tilde{1}}\), therefore:

\[
\begin{cases}
    d(c_{\tilde{n} \times \tilde{1}}, 0_{\tilde{n} \times \tilde{1}}) \geq \tilde{d}_{\text{min}}, \\
    d(c_{\tilde{n} \times \tilde{1}}, 1_{\tilde{n} \times \tilde{1}}) \geq \tilde{d}_{\text{min}},
\end{cases}
\]

which means that \(c_{\tilde{n} \times \tilde{1}}\) contains at least \(\tilde{d}_{\text{min}}\) and at most \(\tilde{n} - \tilde{d}_{\text{min}}\) number of ones. In other words, \(a\) and \(b\) differ at least in \(\tilde{d}_{\text{min}}\) and at most in \(\tilde{n} - \tilde{d}_{\text{min}}\) bits.

For a given codeword \(a\), the first case happens only when \(b = a\) or \(b = 1_{\tilde{n} \times \tilde{1}}\); thus, all the possible \(2^k\) codewords can be paired \((a\) with \(a \oplus 1_{\tilde{n} \times \tilde{1}}\) into \(2^{k-1}\) sets such that only the second case happens for two vectors from different sets. Now assume that we form a matrix by selecting exactly one vector from each set and putting them as the columns, and then converting all the zeros in the matrix into \(-1\) \((A_{\tilde{n} \times 2^{k-1}})\). The columns of \(A\) consist solely of \(\pm 1\) and each two columns differ by at least \(\tilde{d}_{\text{min}}\) and at most \(\tilde{n} - \tilde{d}_{\text{min}}\) elements. Consequently, the absolute value of the inner product of each two distinct columns of \(A\) is upper bounded by \(\tilde{n} - 2\tilde{d}_{\text{min}}\).

Hence, the coherence of the matrix \(A\) when the columns are normalized by the factor \(\frac{1}{\sqrt{n}}\) (all the columns have the same norm and thus, normalization is equivalent to scaling), is upper bounded by \(\frac{\tilde{n} - 2\tilde{d}_{\text{min}}}{\sqrt{n}}\). Recalling a result from [6], [12], we know that it is possible to perfectly recover a \(k\)-sparse vector from noiseless measurements obtained by a sensing matrix with a coherence less than \(\frac{\tilde{n}}{\sqrt{n}} \approx 0.5\). Thus, the mentioned matrix \(A\) is guaranteed to recover \(k\)-sparse vectors for \(k \leq \frac{\tilde{n}}{2(\tilde{n} - 2\tilde{d}_{\text{min}})} + 0.5\).

To generalize the above results to \(p\)-ary codes, there are two difficulties: 1) the definition of \(d_{\text{min}}\) in \(p\)-ary codes just reveals the number of unequal locations in two codewords and unlike the binary case, does not give useful information about the differences and 2) to have a matrix with low inner product among its columns, we need a transformation on the elements such as replacement of the zeros by \(-1\) in the binary case. To solve the latter, we introduce complex matrices by converting the code elements into points on the unit circle in the complex plane while for the first challenge, instead of pairing the code vectors, we have to define larger sets.

Let \(C(\tilde{n}, \tilde{k}; p)\) be a linear \(p\)-ary code over \(GF(p)\) where \(p\) is a power of a prime integer with the minimum distance \(\tilde{d}_{\text{min}}\) such that \(1_{\tilde{n} \times \tilde{1}}\) is a valid code vector. Due to the linearity of the code, all the vectors \(0_{\tilde{n} \times \tilde{1}}, 1_{\tilde{n} \times \tilde{1}}, \ldots, (p - 1)_{\tilde{n} \times \tilde{1}}\) are also codewords. Similar to the binary case, for each two code vectors \(a_{\tilde{n} \times \tilde{1}}\) and \(b_{\tilde{n} \times \tilde{1}}\) with \(c_{\tilde{n} \times \tilde{1}} \triangleq a \oplus b\), one of the following statements holds:\(^3\)

1. \(c = 0_{\tilde{n} \times \tilde{1}}\) or \(1_{\tilde{n} \times \tilde{1}}\) or \(\ldots\) or \((p - 1)_{\tilde{n} \times \tilde{1}}\).
2. \(c \notin \{0_{\tilde{n} \times \tilde{1}}, 1_{\tilde{n} \times \tilde{1}}, \ldots, (p - 1)_{\tilde{n} \times \tilde{1}}\}\); therefore

\[
\begin{cases}
    d(c_{\tilde{n} \times \tilde{1}}, 0_{\tilde{n} \times \tilde{1}}) \geq \tilde{d}_{\text{min}}, \\
    d(c_{\tilde{n} \times \tilde{1}}, 1_{\tilde{n} \times \tilde{1}}) \geq \tilde{d}_{\text{min}}, \\
    \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \ quad 2^0 \times 1\)
addition, assume that the element \(i \ (0 \leq i \leq p - 1)\) is repeated \(N_i\) times in \(c\). For the inner product of \(a_i\) and \(a_j\) we have:

\[
|\langle a_i, a_j \rangle| = |a_i^j a_i| = \frac{1}{n} \sum_{i=0}^{n-1} e^{ij \frac{2\pi i}{n}}(a_i - a_i, \sigma) = \frac{1}{n} \sum_{i=0}^{p-1} N_i e^{ij \frac{2\pi i}{n}} \tag{11}
\]

Since \(e^{j2\pi i/n}\) is the root of \(1 + x + \ldots + x^{p-1}\), for all values of \(\gamma\) we have:

\[
\left| \sum_{i=0}^{p-1} N_i e^{ij \frac{2\pi i}{n}} \right| = \left| \sum_{i=0}^{p-1} (N_i - \gamma) e^{ij \frac{2\pi i}{n}} \right| \leq \sum_{i=0}^{p-1} |N_i - \gamma|, \tag{12}
\]

where we used the triangle inequality for the last part. Recalling inequalities \((7)\) and \((8)\) and by setting \(\gamma = \frac{N_{\text{max}} - N_{\text{min}}}{2}\), we get:

\[
\left| \sum_{i=0}^{p-1} N_i e^{ij \frac{2\pi i}{n}} \right| \leq p \frac{N_{\text{max}} - N_{\text{min}}}{2}
= \frac{p(p - 1)n - p^2 d_{\min}}{2}, \tag{13}
\]

which demonstrates the following upper bound on the coherence of \(A\):

\[
|\langle a_i, a_j \rangle| \leq \frac{p(p - 1)n - p^2 d_{\min}}{2n}. \tag{14}
\]

**Remark 1:** The best choice of \(\gamma\) in \((12)\) which yields the least upper bound for the inner product is the median of the \(N_i\)'s, not necessarily the mean value used in \((13)\); however, the median is not a fixed value and thus, no deterministic upper bound will be derived.

**Remark 2:** To guarantee \(\mu_A < \frac{1}{\sqrt{d}}\) (a sufficient condition for perfect recovery of \(k\)-sparse signals)\([6,12]\) by using the upper bound in Theorem 1, we should have:

\[
\frac{d_{\min}}{n} > \frac{p - 1}{p} - \frac{2}{p^2(2k - 1)} \geq \frac{p - 1}{p} (1 - \frac{4}{kp^2}). \tag{15}
\]

Hence, \(d_{\min}\) should be close to \(\frac{p - 1}{p} n\); i.e., for large values of \(p\), \(d_{\min}\) is almost the same as \(n\). This implies that in order to increase the sparsity order \(k\), we need to increase \(d_{\min}\). The existence and design of such matrices from \(p\)-ary codes will be shown in the next section.

### III. \(p\)-ary Code Design

Due to the existence of a lower bound on the minimum distance of the BCH codes, we focus on the generalized \(p\)-ary BCH codes with large minimum distances. The BCH codes are a subclass of linear cyclic codes (sums and circular shifts of the code-words are also valid code-words) where the elements of the code vectors are taken from a finite field, namely \(GF(p)\) \((p\) is the field size and should be a prime power), and the length of the code-words is \(n = p^{\mu} - 1\) for some integer \(\mu\). Instead of the vector representation, BCH code-words are usually regarded as polynomials of degree \(n - 1\) over the Galois field (elements in the vector are considered as the polynomial coefficients). In this way, a \(p\)-ary \(n \times 1\) vector is a valid codeword if its corresponding polynomial is divisible by a fixed polynomial \(g(x) \in GF_p[x]\) referred to as the code generating polynomial. In order to have the cyclic property in the code, it is necessary and sufficient that \(g(x)\) is a divisor of \(x^n - 1\) \([21]\). Recalling a result from the Galois theory, we know \([21]\):

\[
\prod_{r \in GF(p^\mu)} (x - r) = x^{p^\mu - 1} - 1. \tag{16}
\]

Thus, \(g(x)\), which is a divisor of \(x^{p^\mu - 1} - 1\), should be equal to the product of a subset of \((x - r)'s\) for \(r \in GF(p^\mu)\); i.e., \(g(x)\) can be decomposed into linear factors in this field. This feature is helpful in designing the polynomial by determining its roots.

Let \(\alpha\) be a primitive root of \(GF(p^\mu)\); hence, all the nonzero elements of the field can be written in the form \(\alpha^i\), where \(l\) is a nonnegative integer number. An important result in BCH codes is that if \(\{\alpha^i, \ldots, \alpha^{il}\}\) is a subset of the roots of \(g(x)\) such that \(i_1, \ldots, i_d\) form an arithmetic progression, we have \(d_{\min} \geq d + 1\) \([21]\); if the vector \(\{c_1, \ldots, c_d\}^T\) is a nonzero codeword, we should have \(g(x)\) \(|\sum_{i=1}^{n} c_i x^{i-1}\) and therefore:

\[
\begin{bmatrix}
0 & \cdots & \cdots & \alpha^0 x i_1 & \alpha^1 x i_1 & \cdots & \alpha^0 x i_d & \cdots & \alpha^0 x i_d \\
\vdots & \cdots & \cdots & \vdots & \cdots & \cdots & \vdots \\
\end{bmatrix} = 0_{d \times 1}. \tag{17}
\]

Since \(\{i_1, \ldots, i_d\}\) form an arithmetic progression, each \(d \times d\) sub-matrix of \(H\) is a Vandermonde matrix; thus, each \(d\) selection of the columns are linearly independent which means that at least \(d + 1\) elements in \(\{c_1, \ldots, c_d\}\) should be nonzero (the lower bound on the minimum distance).

In our code design approach, we choose \(g(x)\) such that the set \(\{\alpha^0 x^{p^\mu}, \alpha^{1/p} x^{p^\mu}, \ldots, \alpha^{p^\mu - 1} x^{p^\mu}\}\) is a subset of its roots for an integer \(l < n\). Hence, there exists at least an arithmetic progression of length \(p^\mu - p^{\mu - 1} - \frac{p^\mu - 1}{p - 1}\) among the powers of \(\alpha\) in the roots of \(g(x)\). Consequently, we have:

\[
\frac{d_{\min}}{n} \geq p^\mu - p^{\mu - 1} - \frac{p^\mu - 1}{p - 1} = \frac{(p^\mu - 1)(p - 1)^2 - (p^\mu - 1)(p - 1)}{p(p - 1)}.
\]

To find such a generating polynomial, we construct a polynomial \(h(x) \in GF_p[x]\) (parity check polynomial) without any repeated root such that the roots of \(h(x)\) form a subset of \(T = \{\alpha^0, \alpha^1, \ldots, \alpha^{p^\mu - 1} x^{p^\mu}\}\). Now \(g(x) = x^{p^\mu - 1}\) satisfies all the above requirements for the generating polynomial.

\(^5 x|y\) implies \(y\) is divisible by \(x\).
Except for the trivial cases, the polynomial $\prod_{i=0}^{T_l-1}(x - \alpha^i)$ does not belong to $GF_p[x]$, which shows that the set of the roots is often a strict subset of $T$. The following lemma is a helpful tool for identifying the roots of $h(x)$.

**Lemma 1:** Let $\mathcal{H}^{(n)}_{seq}$ be the set of all binary sequences of length $\tilde{n}$ such that each two 1’s are circularly spaced by at least $\tilde{n} - l - 1$ zeros in between. Furthermore, let $\mathcal{H}^{(n)}_m$ be the set of all decimal numbers for which the base-$p$ representation coincides with a sequence in $\mathcal{H}^{(n)}_{seq}$.

Now, we have:

$$\begin{align*}
\mathcal{H}^{(n)}_m &\subseteq \{0, 1, \ldots, p^{\tilde{n}-1} \cdot \frac{i}{p-1} \}\), \\
\prod_{i\in\mathcal{H}^{(n)}_m}(x - \alpha^i) &\in GF_p[x] \quad (19).
\end{align*}$$

**Proof.** Let $B$ be an element of $\mathcal{H}^{(n)}_{seq}$ with the base-$p$ representation as $(b_{\tilde{n}-1} \ldots b_0)_p$. Since the sequence $(b_{\tilde{n}-1} \ldots b_0)_p$ is a member of $\mathcal{H}^{(n)}_{seq}$, each of the $b_i$’s is either 0 or 1. There are two cases:

1) $b_{\tilde{n}-1} = 0$, therefore

$$\begin{align*}
(b_{\tilde{n}-1} \ldots b_0)_p &\leq (0111111 \ldots)_p \\
&= \frac{p^{\tilde{n}-1}}{p-1} \leq \frac{p^{\tilde{n}-1} + \frac{l}{p-1}}{p-1}. \quad (20)
\end{align*}$$

2) $b_{\tilde{n}-1} = 1$, therefore, the following $\tilde{n} - l - 1$ digits should be zero; $b_{\tilde{n}-2} = \ldots = b_l = 0$

$$\begin{align*}
(b_{\tilde{n}-1} \ldots b_0)_p &\leq (0100000 \ldots)_p \\
&= \frac{p^{\tilde{n}-1} + \frac{l}{p-1}}{p-1} \quad (21)
\end{align*}$$

Thus, we have $\mathcal{H}^{(n)}_m \subseteq \{0, 1, \ldots, p^{\tilde{n}-1} \cdot \frac{i}{p-1} \}\) in addition, for the same $B$, we have:

$$\begin{align*}
pB &= (b_{\tilde{n}-1} \ldots b_0)_p \\
&= b_{\tilde{n}-1}p^{\tilde{n}} + (b_{\tilde{n}-2} \ldots b_0)_p \\
&\equiv b_{\tilde{n}-1} + (b_{\tilde{n}-2} \ldots b_0)_p \mod p^{\tilde{n}-1} \\
&\equiv (b_{\tilde{n}-2} \ldots b_{\tilde{n}-1})_p \mod p^{\tilde{n}-1}. \quad (22)
\end{align*}$$

According to the circular property of $(b_{\tilde{n}-1} \ldots b_0)$, $B' = (b_{\tilde{n}-2} \ldots b_0 b_{\tilde{n}-1})_p$ should be also included in $\mathcal{H}^{(n)}_m$, hence

$$\begin{align*}
a^pB &= a^\gamma B' \in \{a^h\}_{h\in\mathcal{H}^{(n)}_m}; \\
\Rightarrow \{a^pB, a^{p^2}B, a^{p^3}B, \ldots, a^{p^{\tilde{n}-1}B} \} \subseteq \{a^h\}_{h\in\mathcal{H}^{(n)}_m} \quad (23)
\end{align*}$$

In fact, the set of $\{a^pB\}$ is the set of conjugates of $a^B$ with respect to the field $GF(p)$, therefore

$$\begin{align*}
\prod_{i}(x - a^pB) &\in GF_p[x] \quad (24)
\end{align*}$$

which finally results in $\prod_{i\in\mathcal{H}^{(n)}_m}(x - \alpha^i) \in GF_p[x]$. □

The above lemma confirms that the following construction for $h(x)$ fulfills all the required conditions:

$$h(x) = \prod_{h\in\mathcal{H}^{(n)}_m} (x - \alpha^h) \in GF(p)[x]. \quad (25)$$

One of the important conditions to be verified is whether 1_{\tilde{n} \times 1} belongs to the set of codewords. Since the base-$p$ representation of 0 satisfies the required conditions of $\mathcal{H}^{(n)}_{seq}$, 1 = $\alpha^0$ is one of the roots of $h(x)$ which implies that $gcd(g(x), x - 1) = 1$. Due to the definition of $g(x)$, we know

$$\begin{align*}
g(x)|x^n - 1 &\iff (x - 1)(1 + x + \ldots + x^{\tilde{n}-1}) \\
g(x), x - 1 &= 1 \\
\Rightarrow g(x)|1 + x + \ldots + x^{\tilde{n}-1}, \quad (26)
\end{align*}$$

which confirms that 1_{\tilde{n} \times 1} is a valid codeword. The other issue which should be considered is to choose the representatives from each of the sets $\{a, a+(p-1)\}_{\tilde{n} \times 1}$. Since $p \nmid \tilde{n}$, in each of these sets, the polynomial representation of exactly one of the codewords is divisible by $x - 1$. Hence, if instead of $g(x)$, we use $(x - 1)g(x)$ all the desired conditions are fulfilled. In addition, by this choice of the code generating polynomial, the cyclic property of the original code is preserved which is a useful tool for reducing the complexity of the reconstruction method [12]. Also, the additional factor of $x - 1$ increases the lower bound on the minimum distance of the code by 1. Table II summarizes the matrix design steps.

To find the final size of the constructed sensing matrix, we should calculate the value $k$; similar to the discussions in [12], this value is equal to the size of the set $\mathcal{H}^{(n)}_m$. It is shown in [12] that $|\mathcal{H}^{(n)}_m| = O(\gamma^{\tilde{n}-1})$ where $\gamma$ is the largest root of $x^{\tilde{n}-l-1} - x - 1$. Thus, for the $m \times n$ constructed sensing matrix using this code, we have:

$$\begin{align*}
m &= \gamma^{\tilde{n}-l-1} \\
\log_p n &= \log_p \gamma^{\tilde{n}-l} \quad (27)
\end{align*}$$

where $k_{gr}$ represents the threshold for the sparsity order of the sparse vector, up to which we can guarantee the perfect reconstruction. Using the inequality $\gamma \geq \frac{\ln (\tilde{n} - l - 1)}{m - l - 1}$ (see [12]) we can show $\gamma^{\tilde{n}-l-1} \geq \frac{m!}{(m - l - 1)!} \approx p^{m-l-1}$, which implies that $k_{gr}$ increases. To the best of our knowledge, no deterministic design is available yet which by means of RIP guarantees a fixed value $c$ such that $m \leq O(k_{gr}(\log_p n)^{\gamma^{\tilde{n}-l-1}})$. Since, the design principle in our matrices is coherence, it is logical to compare the resulting coherence with the Welch bound (3). For this purpose, we have reported the ratio of the achieved coherence to the Welch bound ($\frac{\gamma^{\tilde{n}-l-1}}{\gamma^{\tilde{n}-l}}$) for some special BCH-based matrices in Table IV. We have used the special case of $\tilde{n} = 2l$, which results in $(p^{2l} - 1) \times \frac{p^{2l}}{p}$ matrices; in fact, for each $p$ we have $\mathcal{H}^{(n)}_m = \{0\} \cup \{p\}^{2l-1} \cup \{p^{l+1} + p\}^{l-1}$. The results in Table IV show that the achieved coherence tends to the Welch bound as $p$ increases.

**IV. Matrix Resizing**

In this section, we introduce two methods to change the size of the previously discussed matrices. In the first method,
by employing the binary matrices, we increase the number of columns (n) for fixed values of m and k; however, this increase does not change the order of $O(k \log n)$. The second method is to change the number of rows (number of samples) which provides us with more options on the number of samples. A summary of these methods is given in Table IV.

### A. Mixing with Binary Matrices

The design of binary matrices with small coherence, due to the non-negative nature of the elements, is a difficult task; the inner product of two binary vectors consists merely of non-negative terms which demonstrates the main difficulty in finding quasi-orthogonal binary vectors in relatively small dimensions. Hopefully, there are at least two known binary matrix structures: 1) Devore’s matrices [11] with $p^2$ rows where p is a prime power and the weight of each column is p and 2) OOC-based matrices introduced in [12] for which the number of rows has larger range of options.

**Lemma 2:** Given a binary matrix $A_{m \times n_1}$ whose columns each have $w_{m}$ nonzero entries with coherence $\mu_A$, and a $w_{m} \times n_2$ matrix $B$ with coherence $\mu_B$ for which the elements have the same absolute value, there exists a deterministic construction for an $m \times (n_1n_2)$ matrix coherence C with $\mu_C \leq \max(\mu_A, \mu_B)$ and normalized columns.

![Diagram](image-url)

**Proof** Here, we explicitly construct C by mixing the two matrices. To form the $l^{th}$ column of C, we first write $l - 1$ as $\alpha n_2 + \beta$, where $\alpha \in \{0, 1, \ldots, n_1 - 1\}$ and $\beta \in \{0, 1, \ldots, n_2 - 1\}$ (in fact, $\alpha$ and $\beta$ are the quotient and remainder of $l - 1$ by $n_2$, respectively). Let $i_1, i_2, \ldots, i_{w_m}$ be the indices of the nonzero locations in the $(\alpha + 1)^{th}$ column of the matrix A. Now the elements of the $l^{th}$ column in C are:

$$
\begin{align*}
&c_{i_1, l} = b_{1, \beta + 1}(r_B \sqrt{w_m}) \\
&c_{i_2, l} = b_{2, \beta + 1}(r_B \sqrt{w_m}) \\
&\vdots \\
&c_{i_{w_m}, l} = b_{w_m, \beta + 1}(r_B \sqrt{w_m}) \\
&c_{s, l} = 0, \quad s \notin \{i_1, \ldots, i_{w_m}\}
\end{align*}
$$

where $[b_{1, \beta + 1}, \ldots, b_{w_m, \beta + 1}]^T$ is the $(\beta + 1)^{th}$ column of B and $r_B$ is the absolute value of the elements of B. The schematic diagram of the above procedure is shown in Fig. 1.

To show the coherence property of C, let $u_{m \times 1}$ and $v_{m \times 1}$ be the $l_1^{th}$ and $l_2^{th}$ columns of C, respectively, where $l_1 - 1 = \alpha_1 \cdot n_2 + \beta_1$ and $l_2 - 1 = \alpha_2 \cdot n_2 + \beta_2$. It is trivial to check that $\|u\| = \|v\| = 1$. To investigate the inner product of the two vectors, we consider the following two cases:

1) $\alpha_1 \neq \alpha_2$, which means that $u, v$ are generated using different columns of A and therefore, they have different patterns of nonzero elements. Since the inner product of different columns of the binary matrix A are less than $\mu_A (w_m A, prior to column normalization), at most $w_m$ of $\mu_A$ of the nonzero elements of $u$ coincide with that of $v$. Moreover, the absolute value of the nonzero elements in both $u$ and $v$ is $\sqrt{w_m}$ (normalized elements...
of B). Consequently, we have:

$$\left\langle \mathbf{u}, \mathbf{v} \right\rangle = \sum_{i=1}^{n} u_i v_i$$

$$\leq \sum_{i=1}^{n} |u_i v_i| = w_m \mu_A \left( \frac{1}{\sqrt{m}} \right)^2 = \mu_B.$$  

(30)

2) $\alpha_1 = \alpha_2$, which means that u, v are generated using the same column of A and therefore, their inner product is the same as the inner product of the respective columns in B (columns $\beta_1 + 1$ and $\beta_2 + 1$):

$$\left\langle \mathbf{u}, \mathbf{v} \right\rangle = \left\langle \mathbf{b}_{\beta_1+1}, \mathbf{b}_{\beta_2+1} \right\rangle = \mu_B.$$  

(31)

Thus, C has normalized columns and its coherence is upper bounded by $\max \{\mu_A, \mu_B\}$.

Although this technique increases $n = n_1 n_2$ (dimension) for the same values of $m$ (number of measurements) and $\mu$ (and consequently, $k_{\gamma'}$), the order of $\log n$ and consequently $\log \frac{n}{m}$ is not improved:

$$\log n = \log n_1 + \log n_2 \Rightarrow O(\log n) = \max \{O(\log n_1), O(\log n_2)\}.$$  

(32)

**B. Kronecker Product**

Let $A_{m_1 \times n_1}$ and $B_{m_2 \times n_2}$ be two arbitrary matrices. Define:

$$C_{m_1 m_2 \times n_1 n_2} = A_{m_1 \times n_1} \otimes B_{m_2 \times n_2}$$  

(33)

where $\otimes$ denotes the Kronecker product of the two matrices; i.e.:

$$c_{\eta, \theta} = a_{\gamma, \tau} b_{\rho, \nu} \tag{34}$$

where $\gamma = (\tau - 1)m_b + \rho, \theta = (\gamma - 1)n_b + \nu$, and $\gamma, \tau, \rho, \nu$ are positive integers not exceeding $m_a, n_a, m_b, n_b$, respectively. Figure 2 shows the schematic diagram of the above Kronecker product.

**Lemma 3:** Assume $C = A \otimes B$.

(i) If A and B have normalized columns, C also has normalized columns.

(ii) $\mu_C = \max \{\mu_A, \mu_B\}$.

(iii) If both A and B satisfy RIP of order k with constants $\delta_{k, A}$ and $\delta_{k, B}$, respectively, matrix C also satisfies RIP of order $k$ with $\delta_{k, C} \leq \delta_{k, A} + \delta_{k, B}$.

The proof of the first two statements can be found in [22], [23] and for the third, the reader is referred to [24].

Now the interesting result which can be achieved by the above operation is the generation of matrices with small coherence and arbitrary number of rows (number of samples). The method in [11] generates matrices with only prime power number of rows; however, using the Kronecker product, we can obtain matrices with number of rows as any product of the prime powers which obviously includes all the positive integers. The disadvantage of this method is the order decrease of $\log \frac{n}{m}$ for a fixed $\mu$ or $k_{\gamma'}$:

$$\frac{\log n_c}{m_c} = \frac{\log n_a + \log n_b}{m_a m_b} = \frac{\log n_a}{m_a} + \frac{\log n_b}{m_b}. \tag{35}$$

Therefore, even if A and B are random matrices ($\frac{\log n_a}{m_a}$ and $\frac{\log n_b}{m_b}$ are close to a fixed multiple of $k_{\gamma'}^{-1}$), the guaranteed performance of C is much worse than the random matrices; e.g., $\frac{\log n_c}{m_c} \approx 0$ for large size values of A and B, while for random matrices that guarantee the recovery of $k_{\gamma'}$-sparse vectors with the same length, $\frac{\log n_{\text{rand}}}{m_{\text{rand}}}$ is close to a multiple of $k_{\gamma'}^{-1}$.

**V. Simulation Results**

In this section, the performance of our proposed class of sensing matrices based on the p-ary BCH codes is compared to the performance of various types of sampling matrices including those proposed in [17] based on the chirp functions, random rows of the DFT matrix, and the realizations of complex-valued Gaussian random matrices.

In order to have a good performance evaluation for our matrices, we have implemented the matrices for three different cases of p (in the p-ary BCH codes); namely, $p = 3, 5, 7$. Moreover, to have a fair comparison, we have considered the same size, $(p^4 - 1) \times p^4$, for the BCH-based matrices, matrices formed by random DFT rows, complex random (independent real and imaginary parts) and chirp-based matrices $(80 \times 729, 624 \times 15625$, and $2400 \times 117649$ for $p = 3, 5, 7$, respectively).
BCH-based matrices are

section In another simulation scenario, we have evaluated the maximum sparsity order of the input signals for which the signal can be recovered almost perfectly from the noiseless compressed measurements. Figures 6 and 7 show the recovery percentage ($SNR_{reconst} \geq 100$ dB) at different input sparsity orders. The matrices in Fig. 6 are similar to those of Fig. 5 and 3; this figure shows a slight advantage of the BCH-based matrices to their closest competitor, the matrices formed by random rows of the DFT matrix. In Fig. 7 we have evaluated the performance of the matrices formed by mixing techniques in Sec. IV. As a representative of the binary mixing technique discussed in Sec. IV-A, we have combined the 64 $\times$ 512 binary matrix with column weight 8 using Devore’s design (field size 8), and the 8 $\times$ 9 complex-valued matrix using ternary BCH codes; the result is a 64 $\times$ 4608 matrix with coherence 0.25.

section Also, random matrices (complex-valued random matrix and random rows of the DFT matrix) of size 64 $\times$ 4608 are used for this figure. Since the number of columns in the chirp-based matrices cannot exceed the square of the number of rows, the size 64 $\times$ 4608 is not realizable in this design; therefore, we have considered the 75 $\times$ 4608 chirp-based matrix with coherence $\frac{1}{\sqrt{75}}$. For the Kronecker product technique discussed in Sec. IV-B, we have combined the 9 $\times$ 27 binary matrix with column weight 3 using Devore’s design (field size 3), and the 7 $\times$ 64 bipolar matrix using binary BCH codes; the result is a 63 $\times$ 1728 matrix with coherence $\frac{1}{\sqrt{63}}$. Although the binary-mixed matrix produces almost the same number of compressed samples for the inputs of 2.5 times larger than the Kronecker-mixed matrix, its performance which is close to the random matrices, is completely superior than the Kronecker-mixed one. Regarding the largest $k$ value for which the recovery percentage is almost one, this matrix outperforms the chirp-based one as well.

section To justify our claim regarding the fast implementation of the recovery algorithm when BCH-based matrices are used, we have compared the required time for recovering the sparse

section In the simulations, the original $k$-sparse vector is generated by first producing a realization of an $n \times 1$ vector of i.i.d. zero-mean complex-valued Gaussian random elements (independent real and imaginary parts) with $\sigma = 1$ and then setting $n - k$ of its elements to zero; the location of $k$ non-zero elements is chosen uniformly at random among all ${n \choose k}$ possibilities. The compressed samples are generated by the mentioned rectangular matrices and then, the samples are subject to Additive White Gaussian Noise (AWGN) with different variances; we refer to the sample to noise power ratio as input SNR. Finally, the original $k$-sparse vector is reconstructed from the noisy samples using Orthogonal Matching Pursuit (OMP); the SNR of the reconstructed signal with respect to the original vector is referred to as the reconstruction SNR. It is shown in [6], [12] that the family of Matching Pursuit (MP) methods will perfectly recover the original $k$-sparse vector from the noiseless samples if the coherence of the sampling matrix is less than $\frac{1}{\sqrt{n}}$.

section To have smooth curves, the results are averaged over 5000 different runs (500 runs for Fig. 4). It is worth mentioning that the coherence of the 80 $\times$ 729, 624 $\times$ 15625 and 2400 $\times$ 117649 BCH-based matrices are $\frac{1}{5}$, $\frac{2}{25}$ and $\frac{1}{8}$, respectively.

section Figure 3 demonstrates the SNRs for the reconstruction of $k$-sparse input signals of size $n = 729$ where $k$ varies from 1 to 30 and the compressed samples are corrupted by AWGN with $SNR = 15$ dB, while Fig. 4 shows similar curves for input size $n = 15625$, where the sparsity orders $150 \leq k \leq 200$ and input $SNR = 30$ dB are considered. These figures show that the BCH-based matrices outperform all other designs, however, the difference between the performance of these matrices and those formed by random rows of the DFT matrix is negligible.

section Figure 5 presents the reconstruction SNRs of 25-sparse 729 $\times$ 1 input signals where the compressed samples are subject to varying noise powers resulting in input SNRs ranging from 0 to 100 dB. This figure again confirms that the BCH-based matrices and those formed by random rows of the DFT matrix perform almost equally and better than the rest. Moreover, the obtained results show that the BCH-based matrices are completely superior than the Kronecker-mixed one. Regarding the largest $k$ value for which the recovery percentage is almost one, this matrix outperforms the chirp-based one as well.

section Fig. 4. The reconstruction SNR vs. sparsity order for the noisy compressed samples with the SNR of 30 dB. The matrices are 624 $\times$ 15625 and the coherence of the 5-ary BCH-based matrix ($p = 5$) is $\frac{1}{25}$.

section Fig. 5. The reconstruction SNR of a 25-sparse signal from its noisy compressed samples for various input SNRs. The matrices are 80 $\times$ 729 and the coherence of the 5-ary BCH-based matrix ($p = 5$) is $\frac{1}{25}$.
The case of $p = 15$ is remarkable. In our last simulation, we use the Lena image of size $65 \times 65$. The original signal has been made sparse ($\frac{1}{4}$) using Haar wavelet coefficients (discarding $\frac{1}{4}$ of the coefficients). Figure 9 depicts the reconstructed images and their Peak Signal to Noise Ratios (PSNR) with respect to the sparse image; in this scenario, random matrices outperform the deterministic designs while 7-ary BCH-based matrix marginally outperform the chirp-based matrix.

VI. CONCLUSION

A new design for matrices with small coherence is investigated which results in complex-valued matrices (except for the special case of $p = 2$). The design is based on the previously studied link between coding theory and compressed sensing. The considered codes are generalized $p$-ary BCH codes that provide large minimum distances among the code vectors. The case of $p = 2$ (special case of bipolar matrices) was

![Fig. 6. The recovery percentage vs. sparsity order where the compressed samples are noiseless. The matrices are $80 \times 729$ and the coherence of the 3-ary BCH-based matrix ($p = 3$) is $\frac{\sqrt{3}}{\sqrt{1728}}$.](image)

previously investigated. Simulation results confirm that the performance of the new matrices has reached the bounds of complex random compressed sensing while they outperform the chirp-type matrices. In addition, we have studied two mixing techniques for combining matrices with small coherence. More specifically, the Kronecker product is considered as a tool for generating sensing matrices with desirable number of rows while the other technique can increase the achievable number of columns.
